## Question 1

*Proof.* Define the function  $h(x) = \frac{f(x)}{g(x)}$ , by the def. of the derivative with limit process:

$$h'(a) = \lim_{x \to a} = \frac{h(x) - h(a)}{x - a}$$

Expanding h(x) and h(a):

$$h'(a) = \lim_{x \to a} = \frac{\frac{f(x)}{g(x)} - \frac{f(a)}{g(a)}}{x - a}$$
$$\Rightarrow h'(a) = \lim_{x \to a} \frac{f(x)g(a) - f(a)g(x)}{g(x)g(a)(x - a)}$$

Applying  $f(x) \approx f(a) + f'(a)(x-a) + E_f(x)$  and  $g(x) \approx g(a) + g'(a)(x-a) + E_g(x)$ , we can rearrange numerator as:

$$f(x)g(a) - f(a)g(x) \approx (f(a) + f'(a)(x - a) + E_f(x))g(a) + f(a)(g(a) + g'(a)(x - a) + E_g(x))$$

$$= f(a)g(a) + f'(a)g(a)(x - a) + E_f(x)g(a) - f(a)g(a) - f(a)g'(a)(x - a) - f(a)E_g(x)$$

$$= f'(a)g(a)(x - a) - f(a)g'(a)(x - a) + E_f(x)g(a) - f(a)E_g(x)$$

Applying the definition of  $E_f(x)$  and  $E_g(x)$ :

$$\lim_{x \to a} \frac{E_f(x)g(a) - f(a)E_g(x)}{g(x)g(a)g(x-a)} = 0$$

we can get overall:

$$h'(a) = \lim_{x \to a} \frac{f'(a)g(a)(x-a) - f(a)g'(a)(x-a) + E_f(x)g(a) - f(a)E_g(x)}{g(x)g(a)g(x-a)}$$

Since  $g(x) \approx g(a)$  when x = a:

$$\Rightarrow \left(\frac{f}{g}\right)' = h'(a) = \lim_{x \to a} \frac{f'(a)g(a) - f(a)g'(a)}{g(a)^2}$$

## Question 2

(a)

Given,

- $f(x) = 2 (x 3) + E_f(x)$ , near x = 3, with  $|E_f(x)| < 1$  one the interval [2, 4].
- $g(x) = x^3 2x^2 + 3$ ; g(2) = 8 4(2) + 3 = 3, g'(2) = 12 8 = 4.

*Proof.* From the initial assumptions, here is the approximation of f(x) near x = 3:

$$f(x) = 2 - (x - 3) + E_f(x)$$

Value of g at f(3):

$$f(3) = 2 - (x3 - 3) + E_f(3) = 2 + E_f(3)$$

Noticing that  $|E_f(x)| < 1$ , then

$$g(f(3)) = g(2 + E_f(3)) = g(2) = 3$$

Then, we can use the Taylor Expansion around f(3) = 2. The first order Taylor expansion for g(f(x)) around x = 3 would be:

$$g(f(x)) \approx g(2) + g'(2) \cdot (f(x) - 2)$$

Then we can sub f(x) in:

$$g(f(x)) \approx 3 + 4(2 + E_f(x) - (x - 3) - 2)$$

$$= 3 + 4(-x + 3 + E_f(x))$$

$$= 3 + 4(-x + 3) + 4E_f(x)$$

$$= 15 - 4x + 4E_f(x)$$

Given E(x) << (x-a) and considering the linearity of  $g'(x): E_{f \circ g} = 4E_f(x)$ . As  $E_f(x)$  is much smaller (x-3), and given  $|E_f(x)| < 1: |E_{f \circ g}| \le 4$ . (b)

Given h(x) is differentiable at x = 0 and h(0) = 3, WTS the bound the error of f(h(x)) near zero.

*Proof.* To precisely bound the error of f(h(x)) near zero, we need two more information:

- Explicit form of  $E_f(x)$
- Rate of Change of h(x)

By knowing these two conditions, we can bound  $E_f(h(x))$  by the following approach:

By definition of Taylor Expansion, we can subsitute

$$h(x) = 3 + h'(0)x + o(x)$$

Where o(x) is the higher order terms that become negligibly small faster than linear.

Then, suppose  $E_f(x) = k(x-3)^n$ , then:

$$E_f(h(x)) = k(h(x) - 3)^n = k(h'(0)x + o(x))^n$$

For evaluation we will only focus on how the "linear" terms in x contribute to  $E_f(h(x))$ .

Assume  $E_f(x) \sim (x-3)^n$  and h(x) = 3 + h'(0)x + o(x), the bound of  $E_f(h(x))$  when x = 0 can be written in the form:

$$|E_f(h(x))| \le |k| \cdot |h'(0)x + o(x)|^n$$

# Question 3

Given, P(t) s.t.  $P(1) = 4, P'(t) = tP(t)^2$ 

# (a) Quadratic Approximation

Proof. Given,

$$P'(1) = 4, P'(t) = tP(t)^2$$

For P'(t) and P''(t), we can get (using the product rule):

$$P'(1) = 1 \times 4^2 = 16$$

$$P''(t) = \frac{d}{dt}[tP(t)^{2}] = P(t)^{2} + 2tP(t)P'(t)$$

Sub t = 1 into P''(t):

$$P^{''}(t) = 4^2 + 2 \times 1 \times 4 \times 16 = 16 + 128 = 144$$

Then we can apply the Taylor Expansion around t = 1, include the small error term E(t-1) s.t. E(t-1) << t-1:

$$P(t) \approx P(1) + P'(1)(t-1) + \frac{1}{2}P''(1)(t-1)^2 + E(t-1)$$
$$P(t) \approx 4 + 16(t-1) + 72(t-1)^2 + E(t-1)$$

Then, we can estimate P(0) and P(-1). Substitute t = 0 and t = -1, we can get:

$$P(0) = 4 + 16(-1) + 72(1)^{2} = 4 - 16 + 72 = 60$$
$$P(-1) = 4 + 16(-2) + 72(4) = 4 - 32 + 288 = 260$$

Noting that E(t-1) is negligible near t=1.

#### (b) Analysis Critical Point at t = 0

Noting that in here we can apply the 2nd derivative test.

*Proof.* From (a), we know that,

$$P''(0) = P(0)^2 \approx 60^2 = 3600$$

Since P''(t) > 0 for t = 0, critical point at t = 0 is a local minimum point.

### (c) Reasonings:

I think in this case the estimation using quadratic approximation for P(0) and P(-1) might likely underestimate the exact values. Such phenomenon aries is because of the quadratic model might not fully capture the exponential growth. Specifically, since  $P'(t) = tP(t)^2$ , the rate of change of P(t) depends on the product of t and  $P(t)^2$ . This might lead to rapid changes in the function's value, particularly when t & P(t) are significantly large. Hence, quadratic approximation might fails to accurately predict the behavior of the function P(t) and underestimate its actual value due to its lack of complexity.
